1.0 INTRODUCTION

The Vasquez Boulevard and I-70 (VBI70) Superfund site is a largely residential area near Denver, Colorado, in which a number of residential properties have concentrations of arsenic and/or lead in yard soil that are elevated over what is considered to be typical for the area. The source of these elevated metal concentrations is not known. Two hypotheses which have been advanced include releases from nearby smelter operations and application of arsenic and/or lead-containing lawn care products or pesticides.

The U.S. Environmental Protection Agency (USEPA), Region 8, is working in cooperation with the Vasquez Boulevard and I-70 (VBI70) Working Group [City and County of Denver (CCOD), the Colorado Department of Public Health and Environment (CDPHE), the Agency for Toxic Substances and Disease Registry (ATSDR), the Colorado Peoples Environmental and Economic Network (COPEEN) and members of the public] to collect data that will help determine which candidate sources are and are not likely to be responsible for the elevations.

This plan for this project, referred to as the Pilot-Scale Soil Characterization Study, is detailed in USEPA (1999). In brief, multiple lines of investigation have been pursued in the hopes of identifying one or more measurements that may be collected from contaminated soil that will be diagnostic of the contamination source. One component of the Soil Characterization Study is the collection of data on the mineralogical and solubility characteristics of lead and arsenic in impacted soils, and comparing those to similar measurements performed in candidate source materials. This report describes the details of this phase of the project, and presents the findings.

2.0 METHODS

2.1 Test Materials

Thirty-five samples were shipped under chain of custody from the USEPA to the Laboratory for Environmental and Geological Studies for analysis. The nature and identity of these samples is summarized in Table 1. These samples consisted on two main groups: candidate source materials and residential soils. The candidate source materials included two commercially available products (PAX and ACME), and several samples of soil or white material collected from the Globe smelter site.

Residential soils included those that were from locations with clearly elevated concentrations of lead and/or arsenic ("focal"), as well as samples from near-by ("adjacent") locations where contamination was low or absent. In addition, a set of sample with high lead but relatively low arsenic levels were evaluated.

Information on the type or significance of these samples was not revealed to the laboratory until all analyses were completed.

2.2 Speciation

Metal speciation of test materials was conducted on a JOEL 8600 electron microprobe (EMPA) at the Laboratory for Geological Studies at the University of Colorado following the laboratories SOP, as outlined in the work plan (USEPA 1999).

2.3 In Vitro Bioaccessability

In vitro bioavailabilty (BAC) tests were conducted using the method developed at the University of Colorado, Boulder and calibrated to EPA's Region VIII Swine Model (Medlin and Drexler 1996, Medlin 1997, Drexler 1997). This method has a high level of correlation to in vivo bioavailability measurements for lead (R^2=0.96), and a moderate correlation for arsenic (R^2=0.86). The method follows a carefully designed laboratory SOP, which is included in the work plan (USEPA 1999).

2.4 Microscopic Perlite Examination

A microscopic examination of a bulk split from each soil sample was performed in an attempt to identify perlite particles. No SOP was furnished to our laboratory nor is there an established method one can reference, however, a brief description of our procedure will follow. A split from each sample was taken using a disposable plastic spoon (1 full teaspoons per sample) and placed in a disposable 14cm, plastic tray. The samples were examined for material having the morphological characteristics of perlite using a Fisher Stereomaster® binocular microscope with 20-40X total magnification. The morphological characteristics of perlite, its highly vesiculated glassy appearance, was first observed in both the PAX sample and a commercial sample of perlite (Black Gold ®) following this procedure. Samples were traversed once, in a grid-like format, recording each positive identification.

2.5 WDSXRF Analyses

Bulk concentration levels for an extensive list of metals in test materials was determined by inductively-coupled plasma-mass spectroscopy (ICP-MS), as described in a separate report. The ICP-MS results for lead and arsenic in the PAX and ACME sample were judged to be unreliable, since the measured values were far from the expected values based on reported content. This was suspected to be a result of difficulties (high dilution error and heterogeneous sample) in measuring non-trace concentration levels by ICP-MS. For this reason, these two samples were analyzed by wavelength dispersive x-ray fluorescence (WDSXRF) for lead and arsenic. Additionally, each of the other 29 samples were analyzed by WDSXRF for Pb, As, Cd and Zn. Samples were analyzed on a PHILIPS PW1400 WDSXRF operating at 60 Kv and 40 mA, following our laboratory SOP. Background corrected peak counts in unknowns are fit to a calibration curve generated from a combination of NIST standards.

2.6 Quality Control

The primary objectives to the series of analyses provided by the University of Colorado are to obtain validated, accurate, and representative results on provided samples. The quality of the data will be assessed based on method QC samples. The type, frequency, and role of QC samples for each analytical method are outlined below. In addition to QC samples, all analyzed materials were subject to method holding times and COC procedures.

The precision of the EMPA speciation will be based on sample duplicates run as required by the SOP, USEPA (1999). Although no criteria have been established for evaluation of precision the objective will be to determine qualitatively how well the method finds the dominant phase(s). The accuracy of the analysis will be estimated based on a statistical evaluation of the point counting following the method of Mosimann (1965). Ninety-five percent confidence values (for frequency of occurrence estimates) are reported in Table 5A for each sample. Again, although no control limits have been determined the data will be used to qualitatively evaluate frequency of occurrence and relative mass estimates.

Quality assurance for the in vitro bioavailability procedure are based on the following QA samples: reagent blank, bottle blank, blank spike, matrix spike, duplicate samples, and control soil(s) with

defined analysis frequency and control limits. The accuracy and precision of the in vitro method itself is provided in references cited in USEPA (1999).

Perlite is a major component of one of the proposed sources to the site contamination. As such the identification of perlite in soil samples could be a fingerprint of that source. No QA was established for the microscopic examination for perlite, however a qualitative estimate of precision can be obtained from duplicate results.

Precision and accuracy of WDSXRF will be evaluated based on duplicate analyses (20% interval) and RPD control limits on NIST standards run with every sample batch, respectively. In addition, method detection limits and equations (with R^2 values) for calibration curves will be provided in Appendix II.

3.0 RESULTS

3.1 Mineral Phase Speciation

3.1.1 Potential Sources Materials

PAX

A sample of the herbicide "PAX" was examined by the laboratory. As shown in Figure 1, this material is primarily composed of perlite, lead arsenate, and arsenic trioxide. Bulk metal concentrations include; 152, 220000, 56000, and 10 mg/kg Zn, As, Pb and Cd, respectively. These measurements are based on average analyses from ICP-MS and WDSXRF. Lead and arsenic values are based on manufactures patent concentrations. Approximately 98% of the lead mass occurs in small (4 um) particles of lead arsenate (PbAsO), of which 73% are liberated and 26% are found rimming other particles. The dominant source of arsenic (89%) are subhedral 12 um particles of arsenic trioxide (As_2O_3), which are typically liberated (98%). A representative photomicrograph of PAX is presented in Photo 1. Minor occurrences of accessory phases include AsSbO, PbMO, $PbCO_3$, and AsMCl. Although perlite contains no metal, the large (89 um) liberated and vesiculated particles dominate the sample (see Photo 2).

Of the other trace metals referenced in the Project Plan (zinc, indium, thallium, antimony, selenium, cadmium, and mercury) only antimony is found concentrated, in a phase(s), with any significant frequency to render it as possible markers for PAX. It is primarily found as AsSbO. A small number of Hg or HgCl particles were also found in this PAX split.

ACME Arsenate of Lead

A sample of "ACME" arsenate of lead, a herbicide, was also speciated. The results are shown in Table 2 and Figure 2. Bulk metal concentrations include; 39, 251300, 694600, and 11 mg/kg Zn, As, Pb and Cd, respectively. These measurements are based on average analyses from ICP-MS and WDXRF. Lead and arsenic values are based on manufactures patent concentrations. The sample is composed entirely of very small (3 um) liberated particles of lead arsenate (PbAsO). A representative photomicrograph of the ACME material is presented in Photo 3. No other metal-bearing phases are found in this sample. No trace element marker phases were found in this material.

Smelter Soils

Four soil samples from the local ASARCO Globe smelter were collected for speciation. Bulk metal concentrations in soils ranged from 190-2470 mg/kg Zn, 7600-27,000 mg/kg As, 2100-5600 mg/kg Pb and 1080-7650 mg/kg Cd. These measurements are based on average analyses from ICP-MS and WDSXRF. As shown in Figure 3, approximately 68% of the lead mass occurs in small (8 um) particles of lead arsenate (PbAsO). Morphologically, 70% of the particles are cemented, 18% are liberated, and 10% are included in other particles. The dominant sources of arsenic (85%) are larger (5-1000 um) subhedral particles of AsCdO, AsMO, As_2O_3 , AsCaO, and AsAlO, Photo 4. In general, 65% of these phases are cemented, while 25% are found liberated. The exception is arsenic trioxide, which is found to be liberated 90% of the time. As shown in Table 4, particles of several accessory phases (slag, PbMO, PbS, CdMO, Se, SeMO, SeHg, and Tl) are also common.

Smelter Material

One sample (SC-00023) of smelter material from the ASARCO Globe smelter was collected. Its bulk chemistry and speciation for metals of concern was only slightly different from the other four soils

collected at the plant site, Figure 3, with perhaps a greater frequency of AsMO and AsAlO. However, in visual appearance it contained a large percentage of a "white" material, Photo 5, that initially was thought to be arsenic trioxide. Neither EMPA nor bulk arsenic analysis supported this observation. A split of the "white" material was made of the sample and analyzed by x-ray diffraction on a Scintag® XRD. The material was confirmed to be a mixture of tridymite (a high temperature form of silicon dioxide) and mullite (a high temperature aluminum silicate). XRD scans and library matching spectra are presented in Appendix II.

3.1.2 Residential Soils

"Focal" Residential Soils

Twelve residential soil samples from the VBI70 site, selected because they contain elevated arsenic concentrations, were collected for speciation. Bulk soil concentrations ranged from 111-574 mg/kg Zn, 23-1490 mg/kg As, 92-1560 mg/kg Pb and 2-12 mg/kg Cd. These measurements are based on average analyses from ICP-MS and WDSXRF. Approximately 70% of the lead mass occurs in small (3 um) particles of lead arsenate (PbAsO), 82% which are found cemented to other particles. As shown in Figure 4, the dominant source of arsenic (57%) are subhedral 16 um particles of As_2O_3. Morphologically, 70% of these particles are liberated and 29% are found cemented to other particles.

When this group is subdivided based on total arsenic concentration a very characteristic trend in mineralogy can be seen. Low-focal samples all have their arsenic relative mass in Fe-Mn-P (Fe oxide, Mn oxide and Phosphate). The intermediate-focal soils are dominated by As_2O_3, and the high-focal are dominated by As_2O_3-PbAsO.

Table 5 summarizes the occurrences of non lead-arsenic accessory phases. Again, when antimony, is observed it is found in AsSbO, and it poorly correlates with bulk arsenic concentrations. Other tracer-

accessory phases observed including Se, SeMO, and Se-In-Cu. Although their abundances are much lower, some similarity to plant soils are noted.

"Adjacent" Residential Soils

Eight residential soil samples from locations adjacent to clearly contaminated soils were collected for speciation. Bulk soil concentrations ranged from 60-396 mg/kg Zn, 9-35 mg/kg As, 39-261 mg/kg Pb and 1-7 mg/kg Cd. These measurements are based on average analyses from ICP-MS and WDSXRF. Approximately 75% of the lead mass occurs in 1-80 um particles of PbMO, Pb-Phosphate, and Pb-Mn Oxide. Morphologically, 70% of the Pb-phosphate and Pb-Mn oxide particles are found cementing other soil particles, while 66% of the PbMO particles are found liberated. The dominant phase (87%) of arsenic is As_2O_3, which occurs in particles ranging from 1 to 195 um in size (see Figure 5). These particles are typically found either cemented and liberated. Because the bulk arsenic concentrations are relatively low for all adjacent samples (therefore total particle counts are low and errors are high) it is difficult to discern a trend in speciation. It would appear however, that low-adjacent soils are similar to low-focal soils, having Fe-Mn-P as their dominant arsenic phases. In contrast to focal soils, both the intermediate and high-adjacent soils have As_2O_3 as their dominant arsenic phase and PbAsO is distinctly sparse.

Again, when antimony, is observed it is found in AsSbO, and it poorly correlates with bulk arsenic concentrations. Other tracer-accessory phases observed including Se, SeMO, and Se-In-Cu , Table 6. Although their abundances are much lower, some similarity to plant soils are noted.

Background Residential Soil

One background, soil sample and a blind duplicate from the VBI70 site, were collected for speciation. Bulk soil concentrations ranged from 137-184 mg/kg Zn, 6-22 mg/kg As, 82-101 mg/kg Pb and 2-3 mg/kg Cd. These measurements are based on average analyses from ICP-MS and WDSXRF. Approximately 98% of the lead mass occurs in small (1-12 um) particles of PbS, which are always

included in slag particles. The dominant source of arsenic (80%) is particles of Fe Oxide that are typically 3-35 um in size (see Figure 6). Morphologically, these Fe oxide particles are found to be liberated 60% and cemented 30% of the time. Antimony is found predominantly in Fe oxide or PbSbO, while the only other tracer-accessory phase observed is Se-In-Cu , Table 7.

High-Lead Soils

Six "high-lead" soil samples from the VBI70 site were collected for speciation. Bulk soil concentrations ranged from 285-784 mg/kg Zn, 14-310 mg/kg As, 236-1209 mg/kg Pb and 6-14 mg/kg Cd. These measurements are based on average analyses from ICP-MS and WDSXRF. Approximately 80% of the lead mass occurs as particles of Pb-Phosphate (1-110 um) , Cerussite (1-25 um) and large particles of lead paint (3-500 um). Morphologically, the Pb phosphate particles are found cemented (64%) while the cerussite particles are more commonly liberated (63%). The paint particles are either found liberated or cemented to other particles. The dominant sources of arsenic (86%) are particles of arsenic phosphate (1-100 um) and Fe Oxide (see Figure 7 and Table 8). Both Pb phosphate and Fe Oxide occur as cemented (64%, 51%) or liberated (35%, 39%) particles, respectively.

The "high lead" soils have a characteristic lack of tracer-accessory phases.

Comparison of Particle-Size Distributions

Table 3 presents a comparison of the particle-size distribution data for the common mineral phases found in potential source materials (PAX, ACME, smelter soils) to those found in residential yard soils. As seen, the mean and median particle sizes of the common phases are generally very similar in residential soils, PAX, and ACME samples, while the particles in plant soils are consistently coarser. The range in particle size for As_2O_3 and PbAsO is greater in residential soils than that observed in either PAX or ACME and narrower than plant soils.

3.1.3 Quality Evaluation for EMPA Speciation

The precision of the EMPA speciation is based on sample duplicates run every 6 samples, which represents an increase in QA from the 1 in 20 required by the SOP.

In general, duplicates (SC00015, SC00046) and (SC00027, SC00043) provided very good to good

reproducibility, finding the same dominant phases in similar frequency. Duplicates (SC00039, SC00114) provided fair reproducibility. Duplicates (SC00065, SC00071) provided very poor reproducibility because total particles counts were very low do to low metal concentrations.

The accuracy of the analysis is estimated based on a statistical evaluation of point counting following the method of Mosimann (1965). Ninety-five percent confidence values (for frequency of occurrence estimates) are reported in Table 5A for each sample. In comparison of results on sample duplicates it is apparent that frequency of occurrence estimates will not fall within the 95% confidence value. However, in all duplicates with elevated metals concentrations the primary phases, representing those metals, are identified (relative mass) within the 95% confidence value. Evaluation of these data would suggest that although the method is not sensitive to small variations in the frequency of observed metal phases, it is highly accurate in the determination of those phases which contribute to a particular metal mass. No quantitative control limits for agreement between duplicates were specified for this project., therefore no corrective actions are required.

3.2 In Vitro Bioaccessability

errors on table

Results

All test materials except the "high lead" samples were analyzed using the in vitro bioaccessability test procedure (BAC) to determine relative lead and arsenic in vitro bioaccessability. Individual sample results are presented in Table 6A, while mean values and ranges are given in Table 9. In general, the soils have a greater lead in vitro bioavailability than any of the three potential sources tested, while the arsenic in vitro bioavailability is most similar to that found in the ASARCO plant samples.

re calculation needed due to errors

Data Quality

Based on the twenty-nine samples requested for BAC testing the laboratory performed or exceeded all of the SOP requirements for frequency and type of QA sample. In addition, all QA samples performed within control limits. A summary of QA results are provided below.

	SOP Analysis Frequency	Project Frequency Performed	Control Limits	Project Limits
Reagent Blank	once per batch	2	<25 µg/L lead	<10 µg/L lead <10 µg/L arsenic
Bottle Blank	5%	7%	<50 µg/L lead	<30 µg/L lead <22 µg/L arsenic
Blank Spike	5%	7%	85-115% recovery	90-100%
Matrix Spike	10%	7%	75-125% recovery	91-95%
Duplicate Sample	10%	38%	20% RPD	4.5% lead 14% arsenic
Control Soil	5%	7%	10% RPD	2%

3.3 WDSXRF Evaluation

Results

WDSXRF results are provided in Table 11 for the four elements analyzed, Zn, Pb, As, and Cd.

Data Quality

Of the thirty-five samples submitted for WDSXRF seven duplicate analyses were performed. Duplicate analyses were within 2%, 18%, 5%, and 32% (Zn As, Pb, Cd) on average. Only 6 of the 28 duplicate concentrations exceeded SOP limits of +/- 30%. No action was taken as these higher values only occurred near instrument detection limits.

WDSXRF accuracy and traceability to NIST are acceptable. Only one element (Cd) during one batch analysis failed the 20% RPD control limit. Average RPD values were 4%, 5%, 7%, and 20% for Zn, As, Pb, and Cd, respectively. No action was taken as two NIST standards were run in that batch and the second standard was within 5% RPD.

4.0 DISCUSSION AND EVALUATION

The USEPA provided a series of questions to facilitate evaluation and interpretation of the data. These questions and the responses are provided below. In order to best answer some of the questions data from previous studies, CDPHE, 1998 and USEPA, 1998.

Questions #1 What are the physical-chemical attributes of arsenic-bearing particles in residential site soils, and how does this depend on the level of arsenic in the sample?

The predominant forms of arsenic in residential soils are As_2O_3, PbAsO, and AsSbO. When residential soil concentrations for arsenic exceed approximately 150 mg/kg (thirty-nine samples), a large percentage of the bulk arsenic is found in As_2O_3 (36 out of 39), and only at the highest arsenic concentrations do AsSbO, and PbAsO play any significant role (2 out of 39 and 6 out of 39, respectively), see Figure 8. Below 150 mg/kg total arsenic, the soils are still often times (15 out of 33) dominated by arsenic trioxide. However, when accounting for all of the soil samples NO correlation is found between bulk arsenic and the relative mass nor frequency of occurrence for any of the arsenic phases common to PAX, (Figures 9 and 10).

Question #2 Do the physical-chemical attributes of arsenic-bearing particles in residential site soils resemble the characteristics in one or more of the potential source materials provided to you (Globe soil, PAX, ACME)? How does this depend on the level of arsenic in the residential soil sample?

If the assemblage (As_2O_3-PbAsO) is considered to be consistent with the herbicide PAX , less than 50% (26 out of 72) of the samples even contain both arsenic forms. Of these 26 samples, only 6 contain As_2O_3+PbAsO in a ratio that could be considered PAX-like. Further, only 9 out of the 72 residential soils could have ACME as a predominant contamination source. Finally, under no

circumstances could the soils from the ASARCO plant (**that have been influenced by the cadmium production**) have contributed significantly to the residential anomaly.

The physical-chemical attributes of the arsenic-bearing particles in residential soils suggest a yet unidentified source which is dominated by As_2O_3. Forty-three of the 72 soil samples with arsenic speciation, support this observation.

2 35 samples provided ?

Question #3 What are the physical-chemical attributes of lead-bearing particles in residential site soils, and how does this depend on the level of lead in the sample?

The predominant forms of lead in residential soils are PbAsO, Pb-Phosphate and Pb-MnOOH. When residential soil concentrations for lead exceed approximately 375 mg/kg (eighteen samples), a moderate percentage of the bulk lead is found in PbAsO (10 out of 18), however, only at the highest lead concentrations does PbAsO play a significant role (3 out of 18), see Figure 8. Pb-Phosphate and Pb-MnOOH dominate the lead mass in most samples (14 out of 18) above 375 mg/kg lead and in 32 out of 42 for the complete data set. Below 375 mg/kg total lead, the soils are never dominated by PbAsO.

I count 12 > 375 mg/kg

Below 375 mg/kg total lead, the soils contain predominantly; Pb-phosphate, Pb-Mn Oxide, paint, PbMO, and PbS.

Question#4 Do the physical-chemical attributes of lead-bearing particles in residential site soils resemble the characteristics in one or more of the potential source materials provided to you (Globe soil, PAX, ACME)? How does this depend on the level of lead in the residential soil sample?

? 35 samples provided

Based upon lead mineralogy only, PbAsO would be considered to be consistent with either the herbicide PAX or the rodenticide ACME, in less than 43% (18 out of 42) of the samples . Of these 18 samples, only 11 contain PbAsO in a sufficient quantity that would suggest a major contribution from either source. Finally, under no circumstances could the soils from the ASARCO plant (**that have been influenced by the cadmium production**) have contributed significantly to the residential anomaly.

The physical-chemical attributes of the lead-bearing particles in residential soils suggest a yet

unidentified (**but very soluble**) source of lead which is now sequestered in Pb-phosphate and Pb-Mn Oxide. Thirty-two of the 42 soil samples with lead speciation, support this observation.

Question #5 Are there any other types of particles that are characteristic of residential site soils that are elevated either in arsenic and/or in lead? If so, are these particles diagnostic of one or more of the potential source materials provided to you?

The following phases are characteristic of the identified source:

$PbSO_4$, $PbCO_3$, $PbCrO_4$, paint chips---------- Paint
PbMO, PbS, Slag, PbFeO, AsFeO, ZnS, ---------- Smelter
SnMO, SnPb, SnCuPb----------Solder
Se, In, Se-In, Se-Cu-In----------Smelter/Electronics

Question#6 Does this approach allow you to identify one or more of the potential source materials as being more likely for the observed contamination in site soils than the other potential source materials?

The data support the conclusion that of the residential soils with highly elevated arsenic and lead concentrations, only a few soils could be, contaminated primarily by PAX or a PAX-like (i.e., lead arsenate {pesticide} and arsenic trioxide {rodenticide}) combination. In fact, the high- adjacent soils, with their observed enrichment in As_2O_3 and lack of PbAsO, would suggest at least a two source mechanism. The current body of information would conclude that the yards are contaminated with an arsenic trioxide source over printed by smelter, paint and perhaps pecticides.

The data clearly illustrate that the ASARCO globe plant soils, as collected, could not have contributed significantly to the residential soil contamination. It is the authors opinion that no surface, soil collected post 1940 could be a potential contributor based on elevated cadmium concentrations. The data also indicate that the presence or absence of perlite can not be used to distinguish potential sources. There is no significant difference in frequency of occurrence of perlite among the residential soils, Figure 9, and even though the plant soils do contain significantly less perlite it is still present.

4.1 Further Questions

The arsenic anomaly in the greater Denver area has been studied intensely for the past decade by numerous individuals, corporations and governmental agencies. Because of the site complexity, both geochemically, environmentally, and socially no one study has been able scientifically determine the source(s) of the contamination. One reason is that no one study has yet addressed all of the complexities. To date, some questions still remain unanswered. I offer them as suggestions for further work.

1). *What would PAX look like mineralogically after 20-30 years?*

2). *Even though available solubility data does not support this scenario: could PAX weather to an arsenic trioxide dominated mineralogy?*

3). *Again, even though available solubility data does not support this scenario: how does one get such elevated arsenic concentrations in soils, after 20-30 years, with* ***normal*** *application rates?*

4). *How does one produce bulk arsenic and lead areal distributions in contaminated yards by application of a product?*

5). *Could the sampling method (used by ASARCO) of compositing front and backyard samples produced the apparent clean/dirty yard scenario?*

Samples used in this study are discrete samples (not composited) and identify some "clean/dirty yard" pattern

6). *Why is this anomaly restricted to the general Globeville area?*

How was this determined - No other neighborhoods sampled so extensively
